Abstract. The ocean's influence on volatile organic compounds (VOCs) in the atmosphere is poorly understood. This work characterises the oceanic emission and/or uptake of methanol, acetone, acetaldehyde, isoprene and dimethyl sulphide (DMS) as a function of photosynthetically active radiation (PAR) and a suite of biological parameters. The measurements were taken following a phytoplankton bloom, in May/June 2005 with a proton transfer reaction mass spectrometer (PTR-MS), from mesocosm enclosures anchored in the Raunefjord, Southern Norway. The net flux of methanol was always into the ocean, and was stronger at night. Isoprene and acetaldehyde were emitted from the ocean, correlating with light ($r_{\text{avcorr, isoprene}}=0.49$; $r_{\text{avcorr, acetaldehyde}}=0.70$) and phytoplankton abundance. DMS was also emitted to the air but did not correlate significantly with light ($r_{\text{avcorr, dms}}=0.01$). Under conditions of high biological activity and a PAR of $\sim 450 \mu\text{mol photons m}^{-2} \text{s}^{-1}$, acetone was emitted from the ocean, otherwise it was uptaken. The inter-VOC correlations were highest between the day time emission fluxes of acetone and acetaldehyde ($r_{\text{av}}=0.96$), acetaldehyde and isoprene ($r_{\text{av}}=0.88$) and acetone and isoprene ($r_{\text{av}}=0.85$). The mean fluxes for methanol, acetone, acetaldehyde, isoprene and DMS were $-0.26 \text{ ng m}^{-2} \text{s}^{-1}$, $0.21 \text{ ng m}^{-2} \text{s}^{-1}$, $0.23 \text{ ng m}^{-2} \text{s}^{-1}$, $0.12 \text{ ng m}^{-2} \text{s}^{-1}$ and $0.3 \text{ ng m}^{-2} \text{s}^{-1}$, respectively. This work shows that compound specific PAR and biological dependency should be used for estimating the influence of the global ocean on atmospheric VOC budgets.

1 Introduction

As the ocean covers some 70% of the Earth's surface area, its potential effect on atmospheric trace gases is enormous. Remarkably, the net primary production of the ocean (48.5 PgC yr^{-1} , $\text{P}=\text{peta}=10^{15}$) is comparable to that of the terrestrial environment (56.4 PgC yr^{-1}) (Field et al., 1998), despite the total amount of biomass in the surface ocean being 100 times less than on land. Ocean biology influences the concentrations of dissolved gases directly (through photosynthesis and emission), and indirectly (through photochemistry of by-products). Such processes lead to an uptake from, or an emission to, the overlying atmosphere for a suite of organic gases (e.g. CO_2 , DMS, isoprene, acetone). These gases are known to significantly impact the atmosphere, influencing ozone photochemistry and aerosol physics (Williams, 2004a, and references therein) even at trace concentrations. Dimethyl sulphide and isoprene have both been established as emissions from the surface ocean to the atmosphere and the distribution of these sources has been investigated by several groups (Bonsang et al., 1992; Kettle and Andreae, 2000; Palmer and Shaw, 2005). Many hundreds of atmospherically important species have been characterised and inventoried from terrestrial sources (Olivier et al., 1994; Guenther et al., 1995), but in comparison, very little work has been done on assessing the emission of volatile organic compounds from the ocean.

It was discovered quite recently that the surface ocean can play an important role in the budgets of organic trace gases, particularly oxygenated species such as acetone (propanone), methanol, and acetaldehyde (ethanal) (Singh et al., 2003). These species have been shown to be ubiquitous in the atmosphere (Singh et al., 2001) and to influence radical budgets

in the upper troposphere (McKeen et al., 1997; Tie et al., 2003; Colomb et al., 2006). Furthermore, the surface ocean has been shown to be a massive reservoir for oxygenated organic species, both indirectly from aircraft measurements (Singh et al., 2000) and directly from ship borne measurements (Williams et al., 2004b).

There have been several global budget estimates for the oxygenated species methanol (Singh et al., 2000; Galbally and Kirstine, 2002; Heikes et al., 2002), and acetone (Singh et al., 1994, 2000, 2004; de Laat et al., 2001; Jacob et al., 2002). The large range of these budget estimates (75–490 Tg yr⁻¹ methanol; 37–148 Tg yr⁻¹ acetone) indicates their currently uncertain nature, and in all these budgets the role of the ocean is the most uncertain factor. In the case of methanol, there is general consensus that methanol is up-taken from the atmosphere to the ocean. The latest budget estimates by Singh et al. (2004) and Jacob et al. (2005) estimate a 10–15 Tg yr⁻¹ sink accounting for approximately 20% of the global budget. It is not yet clear as to what is responsible for maintaining an under saturation of methanol in surface waters, although certain methylotrophic bacteria are known to consume methanol (Kiene, 1993). In the case of acetone, there is remarkably poor agreement concerning the effect of the ocean on the global acetone budget. Using an inverse modelling approach, Jacob et al. (2002) deduced an oceanic source of 27 Tg yr⁻¹ (some 33% of a total bud-

get of 95 Tg yr⁻¹); Singh et al. (2004) estimated a small net sink (in a total budget of 95 Tg yr⁻¹); whereas Marandino et al. (2005) extrapolate an oceanic sink of 48 Tg yr⁻¹ (in a total budget of 101 Tg yr⁻¹), from flux measurements made over the Pacific Ocean. Clearly, further measurements are required in parallel with biological parameters to elucidate these seemingly contrary findings. Moreover, significant median mixing ratios of the reactive species acetaldehyde (204 ± 40 pptv) have been reported by Singh et al. (2003), even after the application of a pollution filter on the dataset. Despite its potential atmospheric importance, no global budget estimate of acetaldehyde has been made to date.

In this study we characterise the effect of the ocean on ambient atmospheric mixing ratios of methanol, acetone, acetaldehyde, isoprene and DMS as a function of light and a suite of biological parameters. The measurements were made under semi-controlled conditions from custom-built mesocosms deployed in the Raunefjord, Southern Norway (see Fig. 1). Mesocosm studies provide a useful interface between laboratory culture studies and open ocean surveys. While laboratory studies cannot generate the community dynamics of natural ecosystems, open ocean studies are complicated by horizontal and vertical mixing in both the air and water phases. Mesocosms therefore offer an excellent opportunity to study natural plankton communities under controlled conditions.

2 Experimental

2.1 The mesocosms

A total of nine polyethylene enclosures (hereafter referred to as mesocosms) were deployed in a fjord at the University of Bergen Marine Biological Station, 20 km south of Bergen, Norway. The construction and operation of such mesocosms has been described in detail elsewhere (Williams and Egge, 1998; Engel et al., 2005), hence only a brief description is given here. The polyethylene enclosures (~ 20 m³ water volume; 9.5 m water depth; ~ 4.3 m³ headspace volume) were filled with unfiltered, nutrient-poor, post-bloom fjord water, which was pumped from 12 m depth adjacent to a raft anchored in the centre of the fjord. The enclosures were covered by gas-tight tents made of ETFE foil (Foiltec, Germany), which allowed for 95% light transmission of photosynthetically active radiation (PAR). In order to stratify the water column and avoid re-introduction of sedimented material into the surface sea layer, 0.6 m³ of freshwater was added and mixed into the upper 5 m of the mesocosms. Throughout the study, the upper 5 m layer was gently mixed by means of an aquarium pump. A phytoplankton bloom consisting of a mixture of diatoms, the coccolithophore *Emiliania huxleyi*, and other prymnesiophytes, was induced by adding nitrate and phosphate in the ratio of 25:1 yielding initial concentrations of approximately $15 \mu\text{mol L}^{-1} \text{NO}_3^-$ and $0.6 \mu\text{mol L}^{-1}$

PO_4^{3-} . The development of the bloom is seen in the profile of Chlorophyll a and the trace gas measurements presented herein were conducted in the aftermath of the bloom (see Fig. 2).

The air flow into several mesocosms was dosed with additional CO_2 in order to also study the effects of elevated CO_2 on marine biology (see PeECE study website at <http://peece.ifm-geomar.de>). In this work, we present measurements only from the duplicate mesocosms which were flushed with ambient air, since these most closely represent the ambient atmosphere of today and are not subject to additional biological responses associated with altering dissolved CO_2 . Based on the rate of the ambient air inflow and the volume of the mesocosm headspace ($\sim 4.3 \text{ m}^3$), the total headspace-air replacement time was 191 min and 170 min for mesocosms 7 and 8, respectively. The inflow and outflow air from both mesocosms was sampled for a suite of volatile organic compounds.

Irradiance was continuously measured every 10 min throughout the study by using a Li-Cor cosine sensor (LI-192SA), mounted on top of the floating mesocosm laboratory.

2.2 PTR-MS

A proton transfer reaction mass spectrometer (PTR-MS) was employed to measure masses 33, 59, 45, 63 and 69, which have been attributed to methanol, acetone, acetaldehyde, DMS and isoprene, respectively. These identifications are in keeping with previous studies although minor contributions from other species, such as propanal to mass 59 cannot be ruled out (Lindinger et al., 1998; Williams et al., 2001). The instrument was positioned on a floating raft to which the mesocosms were attached, in a fjord that opened to the sea some 5 km away (see Fig. 1). Ambient air and air from the headspace of each mesocosm was drawn rapidly ($\sim 4.3 \text{ L min}^{-1}$) and continuously through 0.64 cm diameter and 25 m long Teflon lines shrouded from sunlight. The inlet residence time was less than 12 seconds. A fraction of this flow was sampled online by the PTR-MS. The entire inlet system of the PTR-MS including switching valves comprised of Teflon. Within the instrument, organic species with a proton affinity greater than water are chemically ionised by proton transfer with H_3O^+ ions and the products are detected using a quadrupole mass spectrometer (Lindinger et al., 1998). Further details of the operation of the PTR-MS used here are given elsewhere (Salisbury et al., 2003).

Sequential measurements of ambient air and air from the duplicate mesocosms 7 and 8 were made for 10 min each, in the order – mesocosm 7, ambient air and mesocosm 8. Calibrations were performed during the campaign using a commercial gas standard (Apel-Reimer Environmental Inc.). The total uncertainties of the measurements are estimated to be 21.3%, 15%, 19%, 17% and 14% for methanol, acetone, acetaldehyde, isoprene and DMS, re-

Fig. 2. Time series of Chlorophyll a in mesocosms 7 and 8.

spectively. This includes a 5% accuracy error inherent in the gas standard and a 2σ precision error for all the compounds. Detection limit was defined as the 2σ error in the instrument signal, while measuring methanol at an average mixing ratio of 1 nmol mol^{-1} and each of the other compounds at an average mixing ratio of $0.5 \text{ nmol mol}^{-1}$. The individually calculated precision errors and detection limits were as follows, methanol (16.3%; $0.24 \text{ nmol mol}^{-1}$), acetone (10%; $0.07 \text{ nmol mol}^{-1}$), acetaldehyde (14%; $0.06 \text{ nmol mol}^{-1}$), isoprene (12%; $0.06 \text{ nmol mol}^{-1}$) and DMS (9%; $0.05 \text{ nmol mol}^{-1}$).

2.3 Biological parameters methods

Chlorophyll a (Chl a) was determined in 250 to 500 ml samples filtered on glass fibre filters (GF/F, Whatman). For pigment extraction, filters were homogenised in plastic vials together with 1 ml acetone (100%) and a mixture of glass beads (2 and 4 mm) by shaking (5 min) in a cooled Vibrogen cell mill (Buehler, Germany). Afterwards the extracts were centrifuged (5000 rpm, 10 min, cooled at -10°C). This procedure corresponds, with minor modifications, to the method of Derenbach (1969).

The content of Chlorophyll-a was then determined by means of HPLC (High Performance Liquid Chromatography), using the method of Barlow et al. (1997).

Phytoplankton cell counts were performed with a FAC-SCalibur flow-cytometer (Becton Dickinson) equipped with an air-cooled laser providing 15 mW at 488 nm and with a standard filter set-up. The algal counts were obtained from fresh samples at high flow rate ($100 \mu\text{l min}^{-1}$). The trigger was set on red fluorescence and the samples were run on the cytometer for 300 s. Discrimination of the algal groups was based on dot plots of side-scatter signal (SSC) and pigment autofluorescence (chlorophyll and phycoerythrin).

Samples for enumeration of bacteria were fixed with glutaraldehyde (0.5% final concentration), frozen in liquid nitrogen and stored at -70°C (Marie et al., 1999a). The samples were stained with SYBR Green I (Molecular Probes Inc., Eugene, OR) and analysed according to Marie et

al. (1999b). The discrimination of bacteria groups was based on groups observed in scatter plots of SSC signal versus green DNA-dye (SYBR Green) fluorescence. Fluorescence beads (Molecular Probes) with a diameter of 0.95 μm were added to each sample analysed as an internal reference. Data files were analyzed using EcoFlow (version 1.0.5, available from the authors).

3 Results

3.1 General trends – gas phase species

Figure 3 shows a time series for measurements of methanol, acetone, acetaldehyde, isoprene and DMS measured as masses 33, 59, 45, 69, and 63, respectively. In each case the inflowing ambient air mixing ratio is plotted with the measurements from within mesocosms 7 and 8. Measurements of the inflowing ambient air, including average, median and standard deviation are summarized in Table 1. Variability in the ambient air was highest for methanol followed by acetaldehyde, acetone, isoprene and DMS (see σ values in Table 1). For all species, good agreement can be seen between the two duplicate mesocosms. Where the mixing ratios of a particular species in the mesocosm air were significantly lower than ambient air, we infer that an uptake occurred into the seawater. Conversely when mesocosm air mixing ratios were higher than the inflowing ambient air, an emission from seawater into the air was deduced.

Diel cycles were seen in the mesocosms for acetone, acetaldehyde and isoprene, which exhibited maxima and minima typically from 12:00 p.m.–04:00 p.m. and 12:00 a.m.–08:00 a.m., respectively. In contrast, methanol showed no clear diel cycle in the mesocosms, the variation and absolute values of the mesocosm data being generally suppressed with respect to the ambient air. DMS mixing ratios in the mesocosm air were observed to be generally higher in the evening rather than daytime. We investigate the light and biology dependence of these emissions and uptakes in Sect. 3.2.

3.2 Fluxes of organic species in relation to light (PAR) and biological parameters

At the outset, it should be noted that the emission and uptake fluxes reported here represent the net fluxes from seawater to air and vice versa, inside the mesocosm. Hence the fluxes may be the resultant of separate, strong sinks and sources within the mesocosm system.

Fluxes of the various VOCs were calculated according to Eq. (1),

$$F_{\text{voc}} = \frac{Q}{A} (m_{\text{in,voc}} - m_{\text{out,voc}}) \frac{M_{\text{voc}}}{V_m} \quad (1)$$

where F_{voc} is flux of the VOC in $\mu\text{g m}^{-2} \text{s}^{-1}$, $m_{\text{in,voc}}$ and $m_{\text{out,voc}}$ are the VOC mixing ratios (nmol mol⁻¹) in the inflowing ambient marine air and mesocosm air respectively, Q is the flow rate of the ambient air into the mesocosm in $\text{m}^3 \text{s}^{-1}$, A is the surface area of the seawater enclosed by the mesocosm in m^2 , M_{voc} is the molecular weight of the VOC in kg kmol^{-1} and V_m is the molar gas volume in $\text{m}^3 \text{kmol}^{-1}$ ($=23.233$ at 1013.25 hPa and 283 K).

Figure 4 depicts the time series of the VOC fluxes and PAR in the duplicate mesocosms 7 and 8 while Table 2 gives a summary of the averages, medians and standard deviations of the VOC fluxes in the duplicate mesocosms.

Figure 5 shows daily plankton cell counts of the coccolithophore *Emiliania huxleyi*, the cyanobacterium *Synechococcus sp.*, other nano and picophytoplankton and free-living heterotrophic bacteria. The trace gas measurements covered two subsequent phases of the phytoplankton bloom, from 31 May–5 June – the final phase of bloom decline, and from 6 June–10 June – a post-bloom phase of low phytoplankton standing stocks characterized by an increase in cyanobacterial cell numbers.

The photosynthetically active radiation (PAR) generally ranged from 0 to 1500 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ on most days (Fig. 4). Due to overcast conditions significantly lower daily maxima of ca. 400 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ occurred on the 4 and 10 June.

From Figs. 4, 5 and Table 2 we note that there is good consistency in the magnitude and direction of the fluxes as

Table 2. Comparison of Fluxes in the duplicate mesocosms 7 and 8.

	Units ($\text{ng m}^{-2} \text{s}^{-1}$)					
	Ave.(7)	Ave.(8)	Med.(7)	Med.(8)	σ (7)	σ (8)

Isoprene (E)	0.14	0.14	0.12	0.12	0.12	0.17
DMS (E)	0.30	0.35	0.30	0.27	0.17	0.29

U = Uptake from atmosphere to seawater; E = Emission from seawater to atmosphere

well as the biological parameters in the two mesocosms. The fluxes of the individual organic compounds are examined in detail in the subsequent sections.

3.2.1 Methanol

Throughout the experiment, the net flux of methanol was always into the seawater from the mesocosm air above it. Thus methanol was uptaken both during the day and at night. The average of the Pearson linear correlation coefficients in the duplicate mesocosms (hereafter referred to as r_{avcorr}), calculated for the methanol uptake fluxes and the photosynthetically active radiation (PAR) was 0.18. The period from 31 May–5 June (phase of bloom decline) had stronger methanol uptake compared to 6 June–10 June (post-bloom phase with low phytoplankton abundance). Methanol uptake was generally higher during night-time, indicating that it was not driven by photosynthetic activity. The mean flux in both mesocosms calculated using median values was $-0.26 \text{ ng m}^{-2} \text{ s}^{-1}$, the negative value indicating the direction from air to seawater.

3.2.2 Acetone

During the daylight sections of the experiment, acetone was emitted from the seawater to the air above it, if PAR exceeded $450 \mu\text{mol photons m}^{-2} \text{ s}^{-1}$, while at night it was always uptaken from the air to the seawater. The acetone flux shows good correlation with PAR ($r_{\text{avcorr,acetone}}=0.70$). Furthermore, the emission fluxes were higher in the phase of bloom decline with still relatively high phytoplankton abundances (31 May–5 June) compared to the low biomass post-bloom phase (6 June–10 June). The average of the median uptake fluxes and emission fluxes (uptake from air to sea water and emission from sea water to air) in both mesocosms was $-0.06 \text{ ng m}^{-2} \text{ s}^{-1}$ and $0.27 \text{ ng m}^{-2} \text{ s}^{-1}$, respectively. Overall for the entire measurement period, the flux was an emission of $0.21 \text{ ng m}^{-2} \text{ s}^{-1}$.

3.2.3 Acetaldehyde and isoprene

Acetaldehyde and isoprene were emitted from the seawater to the overlying air throughout the measurement period, with almost no evidence of seawater uptake. The fluxes of acetaldehyde and isoprene show strong correlation with each other ($r_{\text{avcorr}}=0.86$). The flux of acetaldehyde shows greater correlation with PAR ($r_{\text{avcorr,acetaldehyde}}=0.70$) compared to isoprene flux and PAR ($r_{\text{avcorr,isoprene}}=0.49$). There was a decrease in the flux of both acetaldehyde and isoprene during the second phase of the measurement period, from 6 June–10 June. Mean emission flux strengths calculated from median values in the duplicate mesocosms were $0.23 \text{ ng m}^{-2} \text{ s}^{-1}$ and $0.12 \text{ ng m}^{-2} \text{ s}^{-1}$ for acetaldehyde and isoprene, respectively.

3.2.4 Dimethyl sulphide (DMS)

In both mesocosms, DMS was always emitted from the seawater to the air above it. DMS fluxes showed negligible correlation with PAR ($r_{\text{avcorr,dms}}=0.01$). Emission occurred at similar rates irrespective of light intensity, as seen on 4 June, which was particularly overcast. Remarkably, among all the measured organic species' fluxes, only the DMS flux did not decrease in the second phase i.e. from 6 June–10 June. The mean DMS emission flux calculated using median values from both mesocosms was $0.3 \text{ ng m}^{-2} \text{ s}^{-1}$.

4 Discussion

This is the first time that air-sea fluxes of organics have been analyzed and quantified during a mesocosm experiment. From the point of view of trace gas exchange, the mesocosm is a transparent tent, set over an area of ocean surface (circa 3 m^2) and extending from 1.5 m over the surface to 9.5 m below. The tent contains a pocket of gas which is ventilated with ambient air at a constant flow (residence time of the air is 191 min for mesocosm 7 and 170 min for mesocosm 8). The mesocosm experiment differs markedly from the static chamber flux experiments often conducted in soil and plant science. Most importantly, the uppermost

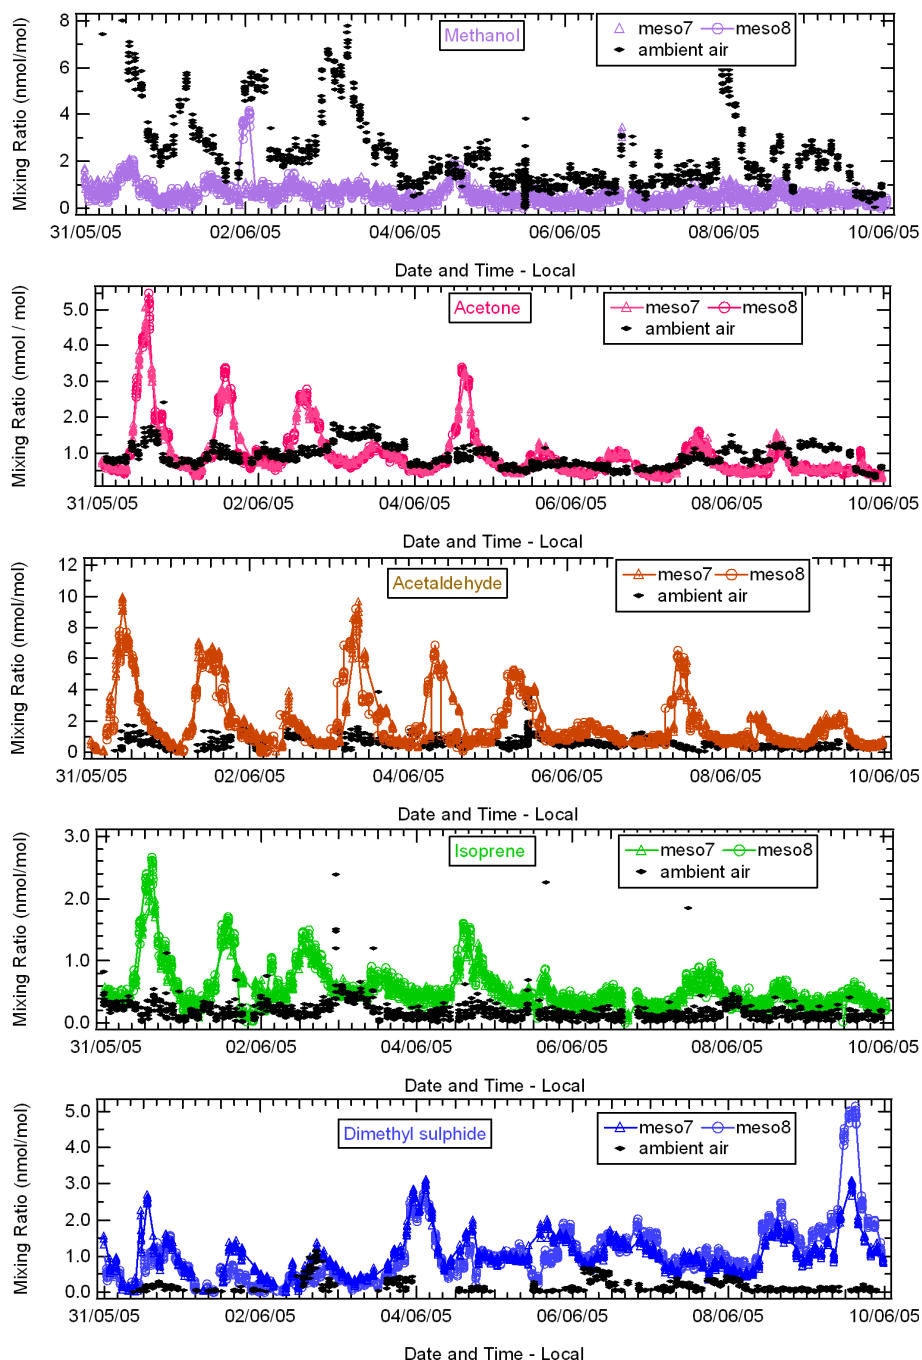

Fig. 3. Time series of methanol, acetone, acetaldehyde, isoprene and DMS from inside and outside the duplicate mesocosms 7 and 8.

5m of seawater in the mesocosm is kept well mixed (see Fig. 6) by use of an aquarium pump (constant flow) and it is from this volume that chlorophyll and DOC measurements are made. In the “real” world many physical parameters may affect the sea-air flux of a given species, for example, the wind speed (as was shown by Carpenter et al., 2004) and mixing down from the ocean uppermost mixed layer. Thus,

in the open ocean mixing, dispersal and advection of the water mass complicate the interpretation of the data. On the other hand, the mesocosm system has low, almost constant air flow, subdued wave activity and possible wall effects from the enclosures, which might cause deviance from conditions in the natural environment. However, the beauty of the mesocosm experiment is that the wind speed and the downward

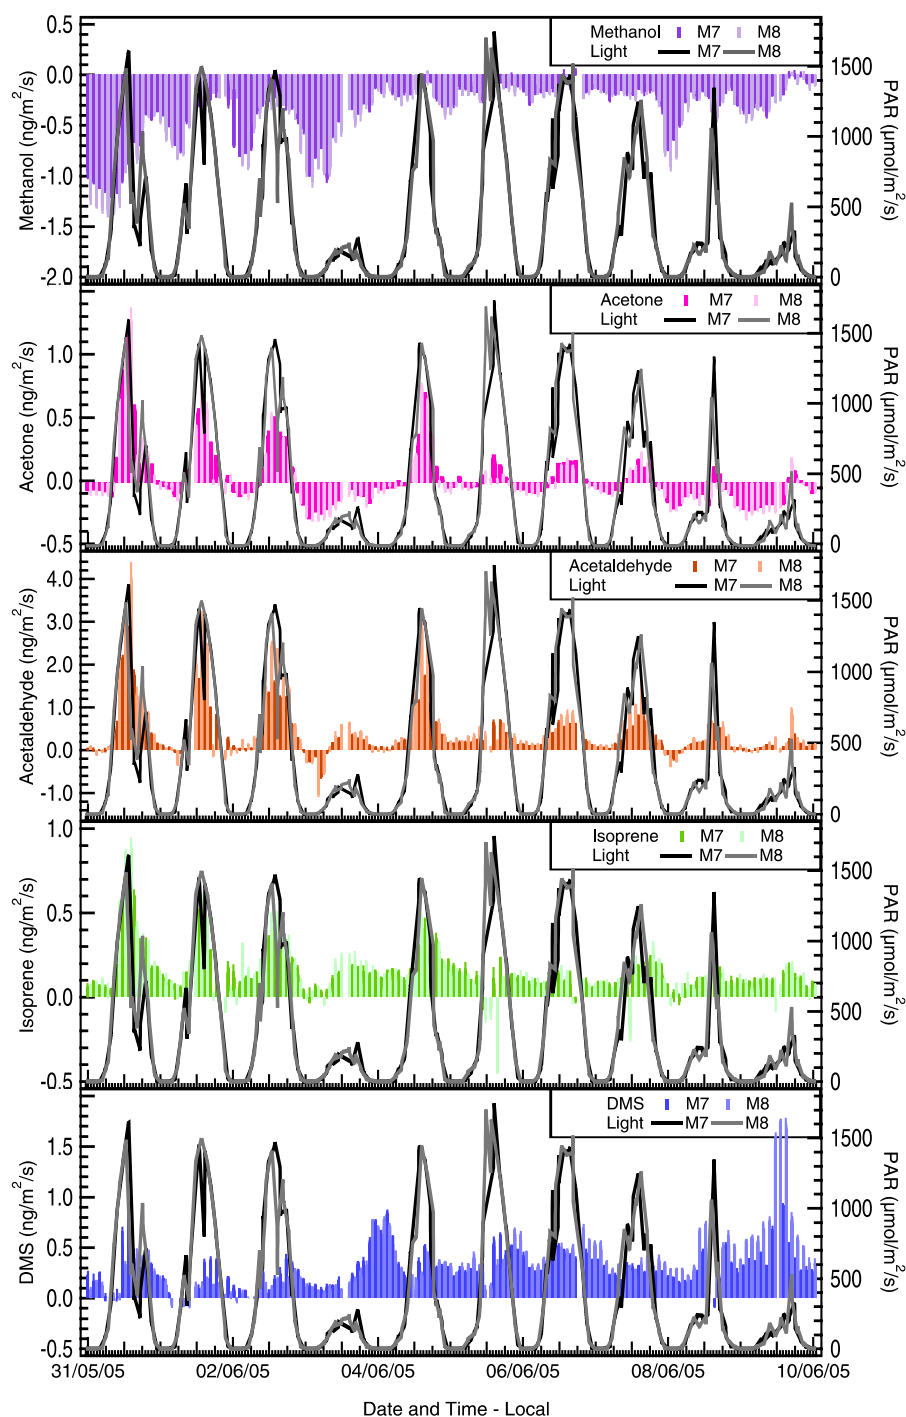

Fig. 4. Flux profiles of methanol, acetone, acetaldehyde, isoprene, DMS and photosynthetically active radiation (PAR) as a function of time in the duplicate mesocosms 7 and 8.

mixing are kept as constant as possible by means of a constant air flow and the effective mixing of the 0–5 m seawater layer, thus allowing other potentially controlling parameters to be investigated. Particularly suited for investigation in the mesocosm system is the significance of: a) ocean bi-

ology producing or consuming organic trace species in the seawater, b) that organic chemicals in the seawater (either directly or indirectly produced by the biology) may be photochemically degraded abiotically to organic gases that subsequently escape to the air. A considerable advantage of

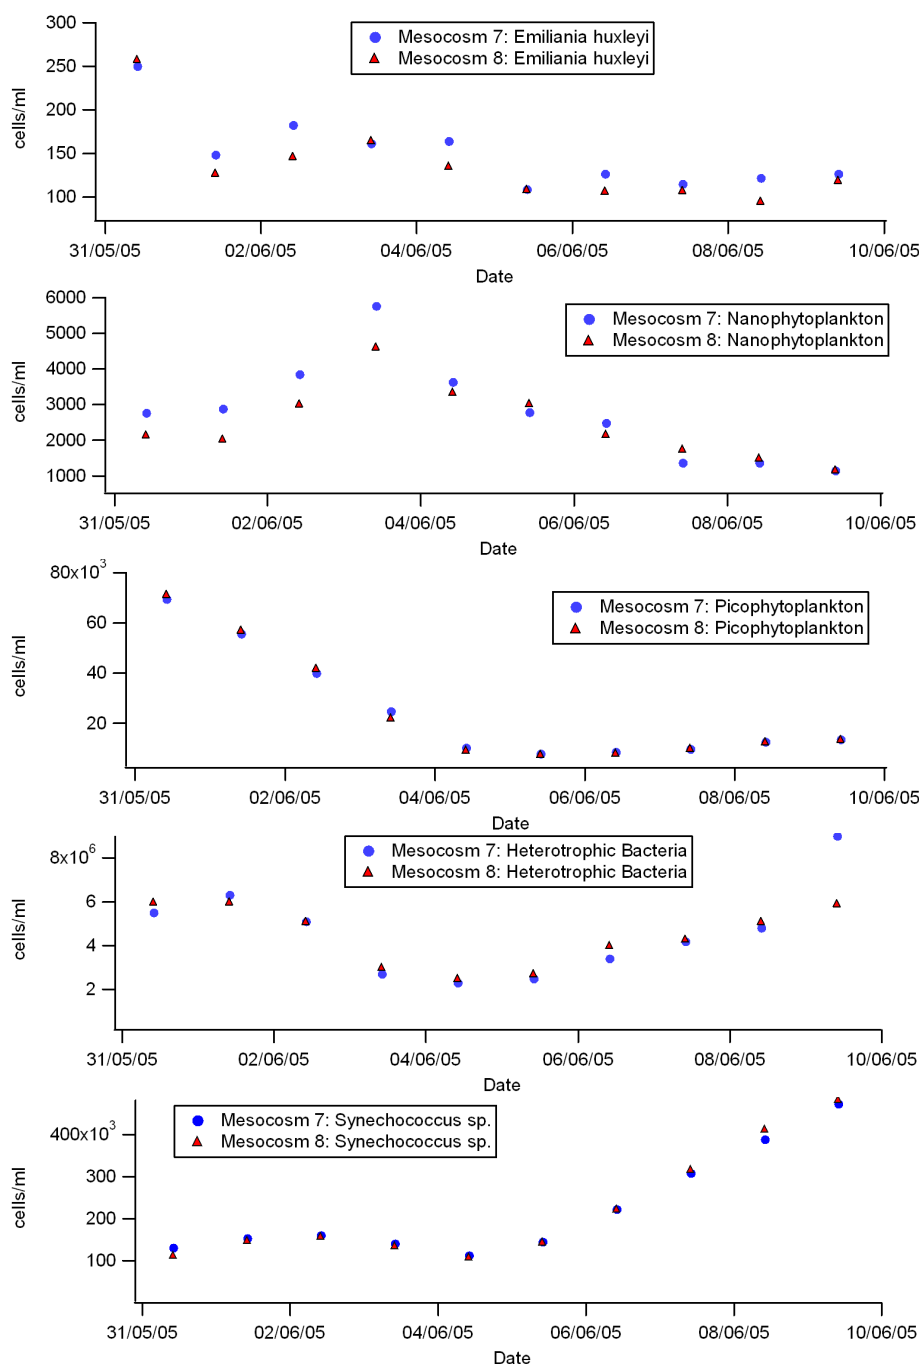

Fig. 5. Daily variation of selected phytoplankton and bacteria over the measurement period for the duplicate mesocosms 7 and 8.

the mesocosm experiment over laboratory studies of single plankton species is that the plankton ecosystem is investigated as a whole, and possible interactions between plankton species (community dynamics) can occur. Furthermore within the mesocosm experiment the biology can be monitored, as opposed to “real world” aircraft studies (e.g. Singh et al., 2003) or coastal studies (e.g. Carpenter et al., 2004).

While previous oceanic flux studies of these compounds have been based on either air-sea flux models (Liss and Mervilat, 1986) or inverse modelling (Jacob et al., 2002; de Laat et al., 2001), in this study we infer fluxes from the difference in direct measurements of the air, before and after controlled interaction with the underlying seawater. Thus, assumptions and uncertainties pertaining to the model based studies are absent in this approach.

Fig. 6. Daily (11:00 a.m.) depth profiles of temperature in the waters (upper 5 m) of mesocosm 7 (above) and mesocosm 8 (below).

Before discussing the correlation of the VOC fluxes with light and ocean biology we would like to examine the potential effects of parameters such as friction velocity, the changing temperature in the mesocosm waters (by possible “greenhouse” heating effect) and possible persistent surface microlayer formation. In the mesocosm system, the influence of any dynamic parameter (e.g. friction velocity) on the VOC fluxes is constant because the air flow through the system is not changing and the water in the first 5 m is constantly mixed. Thus the observed variation in the VOC fluxes cannot be accounted for, in terms of such dynamic parameters. The daily depth profile of mesocosm water temperature is shown in Fig. 6 (the measurements were taken at 11:00 a.m. everyday when PAR is almost at its maximum value for the day, see Fig. 4). Note that the temperature in the water of the mesocosms did not differ significantly for the “sunny” days compared to the overcast days on the 3, 8 and 9 June. This is because the wind buffeting and wave action on the sides of the mesocosm tents coupled with the constant ambi-

Table 3. Change in Henry’s law partitioning due to change in temperature of the mesocosm waters.

Compound	Henry’s law constant ($C_{\text{water}}/C_{\text{air}}$)	Temperature (K)
Methanol	13 003	283
Methanol	11 519	285
Acetone	1430	283
Acetone	1279	285
Acetaldehyde	969	283
Acetaldehyde	862	285

ent air flushing rate of 30 L/min ensures good mixing within the mesocosm system and prevents the accumulation of thermal energy quite efficiently. For the maximum change in the mesocosm water temperature of 2°K observed between different days at 11:00 a.m. (see Fig. 6), the change in the Henry’s law partitioning between the aqueous and gas phase for the OVOCs is shown in Table 3. These results clearly show that the maximum temperature effect would cause only a 13% relative concentration change for methanol, 12% relative concentration change for acetone and 12.4% relative concentration change for acetaldehyde concentrations in the gas phase based on the change in the Henry’s law partitioning. The relative change in the mixing ratios, between a diel minima and maxima is, however, much greater varying between 500%–1500% depending on the VOC and the biological phase (see Fig. 3). Moreover a diel variation time series generated purely by the temperature effect should show no significant difference between the two biological phases. The issue of a persistent surface microlayer is an important one. Such a surface microlayer owing to its surfactant nature, would offer resistance to gas exchange between the bulk water layer and the atmosphere and also be more enriched in Dissolved Organic Matter (DOM) compared to the bulk water, due to inefficient transport and inhibited mixing. In the experimental set up, water in the first 5 m was continuously circulated by means of an aquarium pump and the outlet of the pump was set near the surface in order to inhibit microlayer formation. The fact that species produced in the bulk water such as isoprene, mirror PAR (see Fig. 4) without any significant time phase shift, support the theory that the combined effects of the waves buffeting the mesocosm tents and the internal mixing within the upper 5 m water column in the manner described earlier, prevent the occurrence of a persistent surface microlayer.

From the observations presented in Sect. 3.2 we now examine the light and biology dependence of our derived fluxes within the context of the available literature. In this study, it is extremely difficult to implicate specific biological parameters for the emission or uptake of a particular trace gas, as the biological parameters were measured only once a day and the

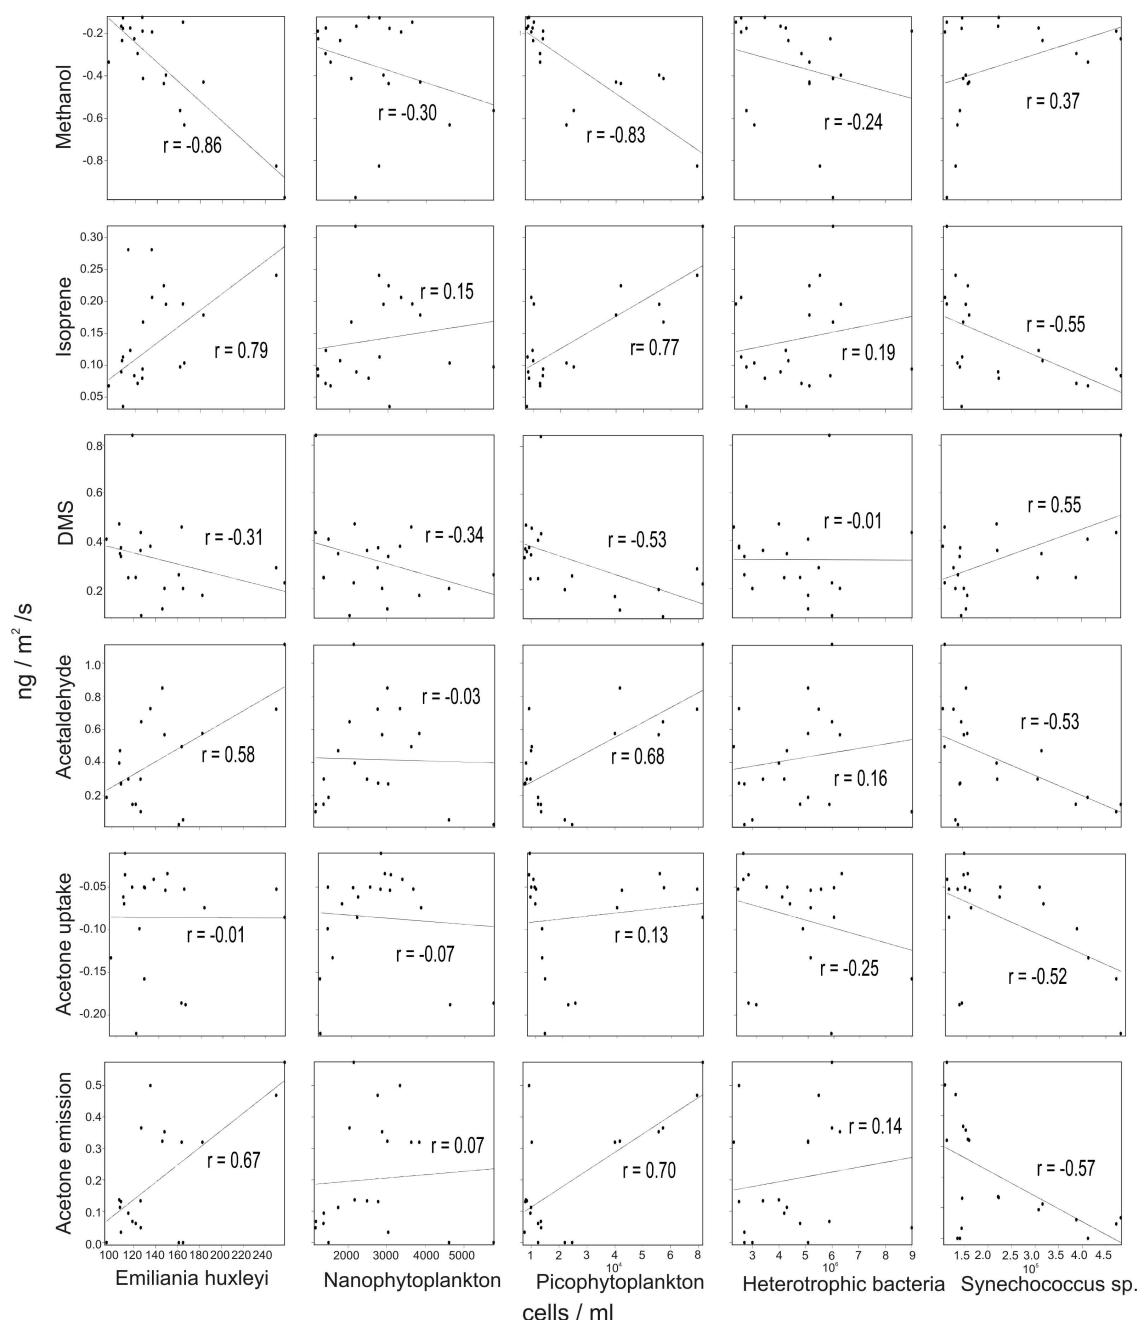

Fig. 7. Regression lines and correlation coefficients (r) between daily averaged VOC fluxes (individual rows) and daily abundance of the biological parameters (individual columns) using data from both mesocosms.

measured flux represents a net process due to possibly different sources and sinks. Nevertheless to give some idea about possible correlations between the VOC fluxes and the few biological parameters measured in this study, we have done a linear regression analysis of the daily averaged VOC flux (row) against the measured biological parameters (column) in both the mesocosms (see Fig. 7). For acetone, the daily emission flux and daily uptake flux has been treated individually. While interpreting the correlations, it should be borne in

mind that at different stages in their life cycle, biological organisms can exhibit different responses and that community dynamics can cause coincidental correlations between individual VOCs and the biological parameters. Furthermore, some of the measured biological parameters are individual species such as *Emiliana huxleyi* and *Synechococcus sp.* while the others like nano plankton (size class), pico plankton (size class) and heterotrophic bacteria are bulk parameters that comprise of more than one species, so appropriate

care should be taken while interpreting the significance of the correlations. Moreover, the chlorophyll content and hence photosynthetic activity depends to considerable degree on the cell size of the autotrophic species, so one cell of *Emiliana huxleyi* will be more potent in producing isoprene (a by product of photosynthesis) than one cell of the other smaller autotrophic species.

Day-time emission of acetone from seawater to the air occurred during the period of bloom decline, when phytoplankton biomass was still high, and comparatively low or absent during the post-bloom period of low phytoplankton abundances. Daily averaged acetone emissions seem to correlate positively with the measured daily abundance of *Emiliana huxleyi* ($r=0.67$) and picophytoplankton ($r=0.70$) while there seems to be negative correlation with *Synechococcus sp.* ($r=-0.57$) (see Fig. 7). Light-dependency of acetone emission was indicated on 4 June, when maximum light intensities below $\sim 350 \mu\text{mol photons m}^{-2} \text{s}^{-1}$ shifted day-time acetone emission to acetone uptake. Can we reconcile these results with the study by Marandino et al. (2005), which reported that acetone is always uptaken from the air to the seawater? It is well established that dissolved organic matter produces acetone by solar irradiation (Zhou and Mopper, 1997). During both phases of plankton succession covered by our measurements, i.e. from 31 May–5 June and 6 June–10 June, the dissolved organic matter (DOM) in the seawater did not show significant variance. Concentrations of dissolved organic carbon (DOC), nitrogen (DON) and phosphorus (DOP) were more or less constant during the measurement period with mean values of $\text{DOC}=100 \pm 7 \mu\text{mol L}^{-1}$; $\text{DON}=8 \pm 3 \mu\text{mol L}^{-1}$ and $\text{DOP}=0.26 \pm 0.04 \mu\text{mol L}^{-1}$ (J. Wohlers, personal communication, 2007). However, since the second phase had considerably less emission of acetone (see Figs. 4 and 5), despite similar PAR and DOM concentrations as during the first phase, the implication is that acetone production in seawater is biologically mediated and light dependent. In the absence or under low activity of the relevant production pathway, acetone consumption in seawater can exceed its production, leading to net acetone uptake by the ocean. This was the situation during the second phase of this study and may have been the cause during the study of Marandino et al. (2005) in the oligotrophic N. W. Pacific.

Net uptake of methanol from air into seawater appears to be attenuated by light, and biological dependence can be inferred from the decrease in the second phase, as plankton abundance and biomass declined. Of course the methanol uptake might have decreased simply because the water was under saturated in the beginning and became gradually more saturated towards the end of the experiment. If uptake was driven solely by physical undersaturation, the same trend would have been also seen in the acetone profiles (see Figs. 3 and 4). Let us nonetheless consider this hypothesis further. The well mixed mesocosm water volume is $\sim 15 \text{ m}^3$. In order to saturate this volume of water at 283°K , and assuming

there is absolutely no methanol in the water to start with; one would need 214 mg of methanol (Taking $H=10\,000$ and $C_{\text{air}}=1 \text{ nmol/mol}$). Using an uptake flux of $1 \text{ ng/m}^2/\text{s}$ (a generous value as can be seen from Figs. 3 and 4), during the period 17 till 30 May, we calculate that $\sim 1.2 \text{ mg}$ methanol would have been available for dissolution in this 14 day period, indicating that based on this criteria alone, the mesocosm water would still be significantly undersaturated before we commenced our measurements with the PTRMS on 31 May. Now, if the mesocosm waters' undersaturation was just a function of "physically driven" undersaturation then there should have been a constant decrease in the uptake flux of methanol over time, because the degree of undersaturation would decrease. What we see however is that on the afternoon of 2 June and 9 June, even for similar mixing ratios of methanol in the ambient air of around 2 nmol/mol , the uptake flux of methanol is in fact more than 1.6 times higher on 9 June. Clearly this is inconsistent with the notion of an undersaturation driven solely by physical parameters and suggests a possible biological contribution to the maintenance of undersaturation in the mesocosm water. What we are suggesting here is that surface waters in the mesocosm are in fact close to equilibrium and that the undersaturation is driven by the biological uptake. A comparison of the deposition velocity found by Carpenter et al. (2004) ($0.02\text{--}0.33 \text{ cm s}^{-1}$; best estimate = 0.09 cm s^{-1}) to that observed in our mesocosm study (circa 0.05 cm s^{-1}) shows reasonable agreement. We interpret the deposition velocity of methanol found by Carpenter et al. (2004) as not indicating an uptake entirely dominated by aerodynamic resistance (interpreted as the turbulent resistance in the atmosphere) even at the reasonably high wind speeds of 8 m s^{-1} . If this were the case (i.e. surface resistance is unimportant) then deposition velocities would be higher (similar to those of HNO_3 ca. $0.5\text{--}1 \text{ cm s}^{-1}$). The comparison of modeled and measured values for methanol wind speed dependencies given by Carpenter et al. (2004) do not show a particularly good match, especially at low wind speeds despite being described a good agreement, perhaps because the model is not fully describing the processes in play and ocean biology contributes to the uptake. As mentioned in the results section, we also observed reduced uptake during daylight hours in the first phase, which was characterized by higher plankton abundance. Heikes et al. (2002) report that methanol has been observed in the headspace of laboratory phytoplankton cultures. Either the biological uptake of methanol from air to seawater is less during the day, or methanol is produced in seawater by phytoplankton during the day or both processes together result in the reduced uptake of methanol, from air to seawater during the day. The second phase has higher *Synechococcus sp.* and free living heterotrophic bacteria but the methanol uptake flux does not increase. This seems to suggest that the cyanobacteria *Synechococcus sp.* and the free living heterotrophic bacteria do not consume methanol significantly under these conditions ($|r| < 0.38$ for both; Fig. 7).

Surprisingly, methanol uptake shows correlation with *Emiliania huxleyi* and picophytoplankton ($|r|=0.86$ and $|r|=0.83$, respectively). We would like to stress that for reasons outlined earlier, this does not necessarily imply that *Emiliania huxleyi* and picophytoplankton uptake methanol by night, although based on our dataset it seems to be a possibility.

Acetaldehyde and isoprene are generally emitted from the seawater to the overlying air. The emissions correlate with both photosynthetically active radiation, as well as the measured biological parameters ($r=0.58$ for acetaldehyde with *Emiliania huxleyi*, $r=0.79$ for isoprene with *Emiliania huxleyi* and $r=0.68$ for acetaldehyde with picophytoplankton and $r=0.77$ for isoprene with picophytoplankton), with decrease in the second phase of the measurements. It should also be noted that some isoprene and acetaldehyde production occurs under overcast conditions and even at night. Like acetone, acetaldehyde is also produced by the photochemical degradation of dissolved organic matter (DOM) in seawater (Zhou and Mopper, 1997), while planktons are known to produce isoprene (Milne et al., 1995). The high degree of correlation between isoprene and acetaldehyde for the entire study ($r=0.86$) and the decrease in both isoprene and acetaldehyde emissions in the second phase, coupled with the insignificant variance in the dissolved organic matter (DOM) during both phases, suggest that there might be some biologically mediated production of acetaldehyde in seawater, from which emission then occurs to the overlying air.

DMS emissions do not seem to depend on light and the emission rate is quite comparable in both phases. It is well established that DMS is produced in seawater both by direct release from phytoplankton and by bacteria and zooplankton mediated grazing (Dacey and Wakeham, 1986; Gabric et al., 2001). Further, Nguyen et al. (1998) have reported appreciable DMS production in seawater during the senescence phase of phytoplankton. Thus, DMS emission in the first phase is probably due to direct release from phytoplankton while grazing processes seem to be responsible for the DMS emission during the second phase.

It is also useful to try and look at correlations amongst the emission fluxes of isoprene, acetone, acetaldehyde, DMS and the uptake fluxes of acetone and methanol with each other during day and night conditions, to try and gauge if they might have common mechanisms linked to their uptake and/or emissions. The Pearson linear correlation coefficient (r_{av}) for all possible pairs among the measured VOC fluxes is shown in Table 4. The strongest correlations seem to be for the daytime emission fluxes of acetone and acetaldehyde ($r_{av}=0.96$), acetaldehyde and isoprene ($r_{av}=0.88$) and acetone and isoprene ($r_{av}=0.85$). Since isoprene is widely established as a biogenic emission, these correlation values support our hypothesis that acetone and acetaldehyde emissions have some biological dependence. The other notable feature is that at least for conditions during our study, DMS emission does not correlate with any of the other VOC fluxes.

In Table 5, we compare the mixing ratios and fluxes measured here with previous studies on methanol, acetone, acetaldehyde, isoprene and DMS in the marine boundary layer. The general level of the ambient air mixing ratios of the oxygenates presented here are consistent with earlier studies, while for isoprene and DMS, they are somewhat higher. Proton transfer reaction mass spectrometry measurements are upper limit estimates because of possibly more than one species contributing to the measured mass. It should be noted that the high mixing ratios of isoprene and DMS in the ambient air were probably due to a local source of macro algae, which were growing near the raft but outside the mesocosms. Isoprene might additionally have been impacted by trees on the coast and the nearby islands.

The relative abundances of the organic trace gases reported in this work and measured using the same instrument, fit with the trend discerned from measurements in previous studies (Zhou and Mopper, 1993; Mao et al., 2006, and other references in Table 5). The trend is: methanol > acetone > acetaldehyde > isoprene \sim DMS. The reported median values also show that the sum of the oxygenates is approximately six times higher than the sum of isoprene and DMS in the marine boundary layer. Interestingly, when fluxes are compared, the sum of the fluxes of oxygenated VOCs ($0.23+0.27-0.26$) is almost a factor of two smaller compared to the sum of isoprene and DMS ($0.12+0.3$).

Compared with direct methanol, acetone and acetaldehyde fluxes reported from a terrestrial pine plantation (Karl et al., 2005), the oceanic fluxes reported here and in previous works (see Table 5) are 2–3 orders of magnitude lower.

Before we discuss the results of a “tentative global extrapolation” for the VOC fluxes measured in this study, we wish to highlight the associated uncertainties of the employed approach. As mentioned earlier, the mesocosm is an artificial set up with low and almost constant wind speed, possible wall losses and subdued wave activity, conditions that may represent significant deviance from “natural” oceanic conditions. For example, methanol uptake flux may be enhanced under the mesocosm conditions while DMS emission flux may be underestimated. Wall losses in the mesocosm cannot be ruled out but if they were the dominant player, one would have seen uptake all the time, i.e. ambient air would be stripped of the compound in the mesocosm by the walls and not the sea. The two most polar compounds we examine are methanol and acetone. While we do observe uptake with methanol, acetone clearly shows emission as well. The wall loss also does not account for the flux changes relating to biology or light. Stratification and mixing of the water column in the mesocosms is designed to simulate open ocean conditions. Stratification prevents re- introduction of sedimented material into the surface sea layer and mixing ensures efficient transport between the bulk and surface waters. Consequently, we believe that parameters associated with the mesocosm design are not the dominant factors controlling the VOC fluxes in the mesocosm, rather ocean biology and

Table 4. Pearson Correlation Coefficient (r_{av}) between the VOC fluxes.

	Methanol	Acetone	Acetaldehyde	Isoprene	DMS

Acetaldehyde	−	−	1	0.58	0.26
Isoprene	−	−	−	1	0.23
DMS	−	−	−	−	1

+ = Day defined as whenever $\text{PAR} > 100 \mu\text{mol m}^{-2} \text{s}^{-1}$; * = Night defined as whenever $\text{PAR} \leq 100 \mu\text{mol m}^{-2} \text{s}^{-1}$

PAR are the primary driving forces of the sea-air fluxes in the mesocosms. Thus, the flux derived from the mesocosms gives an idea of how important ocean biology and PAR can be for the marine emissions and/or uptake of the different VOCs. All the oceanic VOC budget estimates, except perhaps DMS, are based on the few measurements conducted in the “open” oceans in “selected” oceanic regions which have been extrapolated to the global oceans (references in Table 5), although conditions vary widely and vastly from one part of the global ocean to the other. Given this current uncertainty in VOC fluxes from/to the ocean (as highlighted in Table 5), the fluxes from this study can be used to “tentatively extrapolate” for an “indication of the possible global flux” for comparison with previous budget estimates and to ascertain which species are most significant for atmospheric chemistry.

Although this study took place in coastal waters, chlorophyll *a* ($2.28\text{--}1.05 \mu\text{g L}^{-1}$, nutrient values ($\text{PO}_4^{3-} = 0.05 \mu\text{mol L}^{-1}$; $\text{NO}_3^- = 1 \mu\text{mol L}^{-1}$; $\text{SiO}_3^{2-} = 0.25 \mu\text{mol L}^{-1}$, Riebesell et al., 2007¹) and dissolved organic matter (DOM; $97\text{--}110 \mu\text{mol L}^{-1}$) measured in the mesocosm seawater between 31 May and 10 June are representative of vast areas of the global oceans. The up-scaling of the fluxes was based on the entire global ocean surface area of $3.61 \times 10^{14} \text{m}^2$, and all results are summarized in Table 5.

For methanol we estimate a net oceanic sink of 2.97Tg yr^{-1} . This is higher than the 0.3Tg yr^{-1} oceanic sink proposed by Galbally and Kirstine et al. (2002) and lower than the estimates reported by Singh et al. (2003), Heikes et al. (2002) and Jacob et al. (2005). Based on the same

measurements but different models, methanol oceanic sinks of 8Tg yr^{-1} and 15Tg yr^{-1} were proposed by Singh et al. (2003) and Singh et al. (2004), respectively, showing that different model parameterizations give quite different results.

Except for Jacob et al. (2002), all previous studies have estimated a net oceanic sink for acetone. We estimate an emission flux and uptake flux of 3.13Tg yr^{-1} and 0.68Tg yr^{-1} , respectively. It should be mentioned that during the period of our field study in Norway, there was 18 h of daylight and only 6 h of darkness. As established in this study, acetone emissions are influenced by both a critical PAR threshold and biological activities, parameters that have not been incorporated in up-scaling the measurements obtained in this or previous studies.

Measurements of acetaldehyde are currently viewed with some scepticism due to recently reported potential sampling problems for this species. Apel et al. (2003) reported an artefact for acetaldehyde could occur within inlets, even on inert surfaces. Interferences in stratospherically influenced air have been reported by Northway et al. (2004) and Singh et al. (2004) for PTR-MS and GC systems, respectively, suggesting an interfering surface related phenomenon affecting all instruments. Furthermore, acetaldehyde measurements appear to be inconsistent with simultaneously measured species such as PAN and ethane when compared with models (Singh et al., 2004; Lewis et al., 2005). However, by measuring the difference in the acetaldehyde mixing ratios, for the inflowing ambient air and the mesocosm air, we have minimized possible systematic artefacts. As an additional precaution, all the Teflon inlets used for sampling ambient air and mesocosm air, had the same dimensions and were shrouded from sunlight, using black tubing. The case for acetaldehyde emission not being an artefact is strengthened as it correlates with both isoprene and the independently measured biological trends. Our estimate of a global acetaldehyde oceanic source of 2.62Tg yr^{-1} is significantly

lower than the only other estimate of 125 Tg yr^{-1} reported by Singh et al. (2003). It should be noted that a direct emission of acetaldehyde through biological processes as suggested here is a good explanation why acetaldehyde levels were not consistent with ethane (formerly considered the main precursor) in the marine boundary layer.

Estimated global marine isoprene fluxes extrapolated from in-situ measurements range from $0.1\text{--}1.4 \text{ Tg yr}^{-1}$ (Bonsang et al., 1992; Broadgate et al., 1997; Matsunaga et al., 2002; Shaw et al., 2003; Broadgate et al., 2004). The latest estimate based on satellite chlorophyll observations totals 0.12 Tg yr^{-1} (Palmer and Shaw, 2005). This is small in comparison with terrestrial emissions of ca. 500 Tg yr^{-1} and the results of this study (1.4 Tg yr^{-1}) are in agreement with this estimate.

Dimethyl sulphide fluxes reported in this study (3.42 Tg yr^{-1}) are significantly lower than those reported in previous open ocean studies ($25\text{--}104 \text{ Tg yr}^{-1}$; Nguyen et al., 1978; Andreae, 1990; Kettle and Andreae, 2000; Sciare et al., 2000; Huebert et al., 2004). Two factors may contribute to the difference between the flux estimates of this study and previous studies. Firstly, measurements being in the aftermath of a phytoplankton bloom, characterized by depleting nutrients and generally moribund phytoplankton populations, DMS emissions are expected to be low. Alternatively it could be that the predominant biological species during our measurement period were not prolific DMS emitters.

5 Conclusion

From the discussion above it is clear that the air-sea flux of each trace gas depends differently on light and biological activity. Therefore on a global scale, extremely large variations in such fluxes can be expected as a consequence of the range of solar and biological conditions over the oceans. From the extensive ocean studies done on DMS emission fluxes, it is also apparent that seasonality and biological hotspots (such as upwelling at coasts or oceanic fronts) are very important factors. Thus, specifically parameterized models constrained by measurements from locations that represent the varied geographical areas of the global ocean are needed to form more accurate estimates of the oceanic contribution to the global budgets of different volatile organic compounds. This study has shown that PAR and ocean biology can act as quite important players in the emissions of acetone, acetaldehyde and isoprene from the ocean to the atmosphere. Photochemical and global ocean models that consider ethane to be the main source of acetaldehyde in the marine boundary layer may be able to resolve discrepancies between measured and modeled acetaldehyde concentrations by considering the additional biological source. The strong correlations between the daytime emission fluxes of acetone, acetaldehyde and isoprene may also be useful for modeling the air-

sea emission fluxes of these VOCs. Possible methanol uptake at night by phytoplankton species must be investigated in future studies, as this could be a major source of methanol undersaturation in the global oceans. In order to further improve our understanding of the biogeochemical cycling of VOCs at the sea-air interface, we recommend that in future mesocosm experiments, both aqueous and gas phase concentrations should be monitored and the mesocosm air should be actively circulated with a fan to ensure thorough mixing in the gas phase. Further, a more exhaustive suite of biological parameters, measured at a higher frequency than in this study may yield valuable insights for biological production and/or consumption of VOCs in the seawater. Finally, the results have shown that the mesocosm approach is a new and novel technique, particularly suited for clarifying the vast uncertainties that exist in the field of Ocean VOC uptake and emissions and their biogeochemical cycling.

Acknowledgements. We wish to thank K. Schulz for the temperature data from the mesocosms. The authors also thank members of the ORSUM group and PeECE III participants, in particular, R. Hofmann, T. Klüpfel, N. Yassaa and A. Colomb for assistance in installation on the raft. G. Eerdekens and P. Bernhardt are acknowledged for help in designing the hexapus sampling system. V. Sinha would like to thank the International Max Planck Research School for granting a Research Fellowship.

This work was completed as preparation for the OOMPH experiment (<http://www.atmosphere.mpg.de/enid/oomph>).
